Numerous pathologic processes of the ankle can be diagnosed with use of magnetic resonance imaging. Magnetic resonance imaging allows for high-resolution evaluation of not only the osseous structures of the ankle joint but also the soft-tissue structures including muscles, ligaments, and tendons. There are multiple imaging techniques and pulse sequences with which to evaluate the ankle joint. The purposes of this report are to (1) update orthopaedic surgeons on current magnetic resonance imaging techniques and indications for magnetic resonance imaging of the ankle, and (2) elucidate the typical appearance of the normal ankle joint and its common disease entities on magnetic resonance imaging.

Essentials of Magnetic Resonance Imaging

Process of Image Production

The process of image production involves seven steps. (1) The patient is placed supine on the scanner bed. (2) The patient is placed supine on the scanner bed. (3) The patient is placed supine on the scanner bed. (4) The patient is placed supine on the scanner bed. (5) The patient is placed supine on the scanner bed. (6) The patient is placed supine on the scanner bed. (7) The patient is placed supine on the scanner bed.
strong magnetic field of the scanner aligns the protons within the patient’s tissues along the longitudinal axis of the scanner. (3) An electromagnetic pulse is sent into the scanner, allowing for reorientation of the protons in the tissues (typically 90° to the external field). (4) The electromagnetic pulse is turned off, and the protons are allowed to relax to their original state. (5) As the protons relax, they emit a radiofrequency signal that is picked up by the antenna in the scanner. (6) This relaxation radiofrequency signal is processed by the computer (Fourier transformation). (7) Software programs are used to create the images in multiple orthogonal planes.

Definitions
T1 indicates the amount of time required for 63% of the protons to return to their preexcited state and is a measure of the longitudinal relaxation of the protons. T2 indicates the...

Mal. = lateral malleolus, Med. Mal. = medial malleolus, PB = peroneus brevis, PL = peroneus longus, ATFL = anterior talofibular ligament, and PTFL = posterior talofibular ligament.
amount of time for 63% of the protons to “dephase”—that is, to start precessing at frequencies different from the applied electromagnetic pulse. This decay rate is a characteristic of the tissue.

Types of Pulse Sequences
By manipulating the strength of the radiofrequency pulse, how frequently it is applied, and how long after the pulse the relaxation energy is measured, the images can be weighted to emphasize the T1, T2, or gradient-echo characteristics of a tissue (Table I).

T1-weighted images (Fig. 2-A) offer the best anatomic detail and are used to evaluate anatomy, fractures lines, and other osseous detail.

T2-weighted images (Fig. 2-B) have a lower resolution; however, they are more sensitive to pathologic changes in the tissue, particularly to any process in which cells and the extracellular matrix have increased water content.

Fat-suppressed T2-weighted fast-spin-echo and STIR (short tau inversion recovery) images (Fig. 2-C) represent T2-weighted images that are acquired with a pulse sequence to suppress fat and accentuate fluid. Therefore, these sequences are most sensitive for highlighting pathologic changes and edema in the bone and soft tissues.

Gradient-echo pulse sequences are intermediate views between T1-weighted and T2-weighted images. Gradient-echo images are excellent for the evaluation of articular cartilage integrity and the assessment of hemorrhage, which produces a signal drop out.

Basic Steps in Image Interpretation
The basic steps to evaluate a magnetic resonance image of the ankle joint systematically include the following. (1) Determine the pulse sequence of all the images (Tables I and II). (2) Look for normal anatomy on T1-weighted and gradient-echo images and evaluate for the presence of any abnormal structures. Evaluate all structures described under “Normal Anatomy of the Ankle on Magnetic Resonance Imaging” below. (3) Confirm that all tissues are homogeneous

| TABLE II Tissue Characteristics on Magnetic Resonance Imaging* |
|-------------------|-------------|-------------|-------------|-------------|-------------|
| Tissue Type       | T1          | T2†         | STIR‡       | Gradient Echo |
| Cortical bone     | Very low    | Very low    | Very low    | Very low    |
| Red marrow        | Intermediate| Intermediate| Intermediate| Intermediate|
| Yellow marrow     | High        | Intermediate| Very low    | Low         |
| Fat               | High        | Intermediate| Low         | Intermediate|
| Fluid             | Low         | High        | Very high   | Intermediate|
| Muscle            | Intermediate| Intermediate| Low         | Intermediate|
| Ligaments and tendons | Low     | Low         | Very low    | Very low    |
| Physeal scar      | Low         | Low         | Low         | Low         |
| Hyaline cartilage | Intermediate| Intermediate| Intermediate| Intermediate|

on T1-weighted images. If they are not, check the T2-weighted and T2-weighted fat-suppressed images to verify any abnormality. (4) Evaluate the T2-weighted images for areas of increased signal due to increased water content (which is sensitive, but not specific, for an abnormality). (5) Correlate the magnetic resonance imaging findings with the clinical history to determine the most likely diagnosis.

**Figs. 9 through 12** Sagittal T1-weighted images showing normal anatomy of the ankle from lateral (Fig. 9) to medial (Fig. 12). EHL = extensor hallucis longus, PTT = posterior tibial tendon, FDL = flexor digitorum longus, FHL = flexor hallucis longus, EDL = extensor digitorum longus, Med. Mal. = medial malleolus, Lat. Mal. = lateral malleolus, PB = peroneus brevis, and PL = peroneus longus.
Normal Anatomy of the Ankle on Magnetic Resonance Imaging
Axial Images (Figs. 3 through 8)

The axial sequences are important in evaluating the ankle because they demonstrate many structures better than do sagittal or coronal images. These images are reviewed systematically from superior to inferior cuts. Because most structures are seen on cross sections, it is important to follow each structure from image to image throughout its entire course.

Muscles and tendons: The tibialis anterior and the extensor hallucis longus can be seen as the two most anteromedial structures at the level of the ankle joint superficial to the anterior neurovascular bundle. The extensor
The digitorum longus has a broad appearance at the level of the ankle joint and lies more laterally than the extensor hallucis longus. The peroneus tertius is sometimes difficult to visualize because of its small cross section; however, it is the most lateral tendon on the anterior aspect of the ankle.

The posterior tibial tendon lies just posterior to the medial malleolus at the level of the ankle joint. The flexor digitorum longus is posterior to the posterior tibial tendon and medial to the posterior neurovascular bundle. The flexor hallucis longus has a broad muscle belly at the level of the ankle joint and lies lateral to the posterior neurovascular bundle.

The flexor hallucis longus is seen well between the two tubercles of the posterior process of the talus. The peroneal tendons are seen just posterior to the fibula. The peroneus brevis lies against the osseous surface of the fibula, and the peroneus longus is more superficial at the level of the ankle joint. The Achilles tendon comprises the tendinous insertion of the soleus and the gastrocnemius muscles of the calf. It inserts on the calcaneal tuberosity and is the most posterior midline tendon structure at the level of the ankle joint. The Achilles tendon normally has an oblong shape.

Ligaments: The anterior and posterior-inferior tibiofibular ligaments constitute the syndesmotic ligament complex at the level of the ankle joint. The convex articular surface of the distal end of the fibula articulates with a concave facet at the inferior lateral aspect of the tibia. This distal tibiofibular joint is stabilized by the interosseous ligament between the tibia and the fibula and by the anterior and posterior-inferior tibiofibular ligaments that extend from the fibular notch of the tibia to the distal end of the fibula.

The anterior talofibular ligament and the posterior talofibular ligament, along with the calcaneofibular ligament, constitute the lateral collateral ligament complex of the ankle (see “Coronal Images” below). The anterior talofibular ligament and the posterior talofibular ligament extend anteriorly and posteriorly from the fibula to the talus. The anterior talofibular ligament is a flat band that extends anteromedially from the anterior margin of the lateral malleolus to the neck of the talus. The posterior talofibular ligament extends medially and slightly posteriorly from the posterior tip of the lateral malleolus to the posterior lateral process of the talus.

Neurovascular structures: The anterior neurovascular bundle, which includes the anterior tibial artery, anterior tibial vein, and deep peroneal nerve, is slightly lateral and deep to the extensor hallucis longus. The posterior neurovascular bundle, composed of the posterior tibial artery, vein, and nerve, lies between the flexor digitorum longus and flexor hallucis longus posteriorly.

Sagittal Images (Figs. 9 through 12)
Sagittal images allow most structures to be viewed longitudinally along their courses. These images should be viewed systematically from lateral to medial.

Muscles and tendons: The posterior tibial tendon can be identified as the first structure just posterior to the medial malleolus. On the sagittal image, the longitudinal course of this tendon can be identified as it heads for its primary inser-
tion on the tuberosity of the navicular. The flexor digitorum longus and flexor hallucis longus can be identified as the two tendons posterior to the posterior tibial tendon; they show a longitudinal and oblique course in this plane. On the sagittal images, the flexor hallucis longus is the deepest posterior compartment muscle, lying against the bone. The Achilles tendon can be followed to its insertion on the calcaneal tuberosity. If
the retrocalcaneal bursa contains fluid (as from inflammation), it can often be identified on T2-weighted images.

**Ligaments**: Coronal and axial images are better for identifying these structures.

**Coronal Images (Figs. 13 through 17)**

Coronal images should be viewed systematically from posterior to anterior. These images are useful for evaluating the medial and lateral ligamentous complexes of the ankle.

**Muscles and tendons**: Although the coronal images are not the ideal images for identifying muscles and tendons, the posterior tibial tendon, flexor digitorum longus, and flexor hallucis longus can be identified with relative ease. The posterior tibial tendon can be identified as a longitudinal dark signal on T1-weighted images just posterior to the medial malleolus. The broad origin of the flexor hallucis longus from the posterior two-thirds of the fibula and the interosseous membrane can be easily identified on the coronal images.

**Ligaments**: The medial collateral ligament complex of the ankle, or deltoid ligament, has superficial and deep layers. The superficial layer consists of the tibionavicular ligament and the tibiocalcaneal ligament. The tibionavicular ligament originates from the medial malleolus and attaches into the tuberosity of the navicular. The tibiocalcaneal ligament is often seen as a thick, dark band extending from the medial malleolus inferiorly to the sustentaculum tali of the calcaneus. The tibiotalar ligament constitutes the deep layer of the deltoid ligament. It extends from the medial malleolus to cover the entire nonarticular medial side of the talus. The lateral ligament complex of the ankle consists of the calcaneofibular ligament, anterior talofibular ligament, and the posterior talofibular ligament. The calcaneofibular ligament is
T1-weighted sagittal image showing Achilles tendinosis. The tendon is thickened with focal anteroposterior enlargement. Note the edema in the fat around the intact tendon.

Fig. 30
Evaluation of Pathologic Conditions of the Ankle

Ligaments

Ankle sprains are common injuries, varying from mild to severe; lateral ligament injuries are more common than medial ones. Ligament injuries are best evaluated on T2-weighted and T2-fat-suppressed weighted magnetic resonance imaging scans. These images usually show increased signal, signifying edema and fluid collection representative of trauma. Discontinuity in the ligament on T1-weighted and T2-weighted images signifies disruption.

The anterior talofibular ligament is the weakest and most vulnerable of all ankle ligaments. Tears in this ligament are best diagnosed on axial images (Figs. 18 and 19). The second most common pattern of ankle injury is a combined injury to the anterior talofibular ligament and calcaneofibular ligament. Isolated tears of the calcaneofibular ligament are extremely uncommon. Unlike the anterior talofibular ligament, tears of the calcaneofibular ligament are best seen on the coronal T2-weighted and T2-fat-suppressed images (Fig. 20).

Isolated injuries of the deltoid ligament are uncommon. The deltoid ligament injuries are best viewed on coronal T2-weighted and T2-fat-suppressed images (Fig. 21). Therefore, magnetic resonance images must be carefully correlated with clinical examination to avoid false-positive results.

Posterior Tibial Tendon Dysfunction

Posterior tibial tendon dysfunction is the most common cause of adult-onset flat-foot deformity. The pathophysiology involves dysfunction and degenerative changes within the tendon. Posterior tibial tendon tears can be classified into three types on the basis of their characteristics on magnetic resonance imaging (Table III). A type-I tear has longitudinal splits in the tendon resulting in hemorrhage, scar formation, and thickening of the tendon. The posterior tibial tendon can be enlarged to four to five times the size of the adjacent flexor digitorum longus (Figs. 22 and 23). Type-II tears are more severe, with longitudinal splits that cause the tendon to attenuate to one-half to one-third of its original thickness. Type-III tears represent a complete rupture of the tendon with retraction of the stump and a visible gap. Posterior tibial tendon tears are best diagnosed on T2-weighted and T2-fat-suppressed axial images.

Peroneal Tendon Disorders

Magnetic resonance imaging is a valuable tool with which to diagnose a peroneal abnormality. The axial images are ideal...
for revealing evidence of tendon sheath effusion and synovitis, as is often seen in peroneal tendinitis\(^9\) (Figs. 24 and 25). Peroneal tendon ruptures, although uncommon, may occur as a result of trauma or inflammatory arthritis (Fig. 26). Some believe that peroneal tendon tears occur secondary to chronic abrasion of the tendon against the posterior ridge of the fibula\(^10\). Chronic peroneal tendon subluxation or instability has been reported with attenuation of the superior peroneal retinaculum and a shallow retrofibular groove\(^6\). Both of these are well visualized on T1-weighted axial images (Fig. 27).

**Achilles Tendon Problems**

The Achilles tendon does not contain a synovial sheath but rather is invested by loose connective tissue\(^8\). Normally, it should have a flat or concave anterior margin with a low, homogeneous signal on axial images. In Achilles tendinosis (Fig. 28), there is a loss of the sharp tendon interface with the surrounding tissues, and the tendon may appear thickened and heterogeneous. Chronic tendinosis can lead to tendon rupture, frequently at 2 to 6 cm proximal to its insertion into the calcaneal tuberosity\(^11\) (Fig. 29).

**Cysts**

A ganglion cyst occurs in the setting of degeneration in an area of the joint capsule or tendon sheath and eventually results in an outpocketing of mucoid degeneration. The cyst shows high signal intensity on T2-weighted images consistent with fluid (Fig. 30). On T1-weighted images, the cyst shows intermediate intensity. Cysts may also show rim enhancement with gadolinium contrast infusion.

**Osteochondral Defect**

*(Osteochondritis Dissecans)*

Separation of articular cartilage from its underlying subchondral bone is known as an osteochondral fragment or osteochondritis dissecans. These lesions are often initially misdiagnosed clinically as ankle sprains\(^12\). Lateral lesions occur more commonly and present in more advanced stages than do medial lesions\(^12,13\) (Figs. 31 and 32). A stable lesion is defined as one having intact cartilage with a solid fibrous attachment. An unstable lesion has either synovial fluid or granulation tissue at the interface with the subchondral bone\(^14,25\).

**Fig. 33**

Figs. 33 and 34 T1-weighted (Fig. 33) and fat-suppressed T2-weighted (Fig. 34) sagittal images showing osteonecrosis of the talus. Much of the talar body appears to be involved.
Osteonecrosis of the Talus

Magnetic resonance imaging is believed to be more sensitive than scintigraphy in diagnosing osteonecrosis of the talus and has the added advantage of better anatomic resolution\(^\text{16}\). T2-weighted images typically show low signal intensity in the talar dome consistent with necrosis and early changes of the classic double-ring sign (Figs. 33 and 34)\(^\text{16}\). Because there is a risk of osteonecrosis after talar neck fractures, open reduction and internal fixation with titanium screws is recommended to minimize the metal artifact on postoperative magnetic resonance imaging studies (Fig. 35).
